

## Mafs – Plan 9 userspace file systems

Mafs wants you to be able to understand it, so you can be self-sufficient and fix a crash at two in the morning or satisfy your need for speed or a feature. This empowerment is priceless for those with skin in the game. It provides a reference implementation for creating use-case optimized filesystems.

Mafs is a user space file systems to provide system stability and security. It is based on kfs. It maintains copies of all metadata, creates a copy on any data write and writes to the disk lazily. These equate to greater throughput, the prevention of disk fragmentation, and the display of a recovery path on unsafe shutdowns.

As this document aims to also provide working knowledge, it gratuitously uses the actual commands and the relevant C data structure definitions to convey information.

### Mafs Workflow

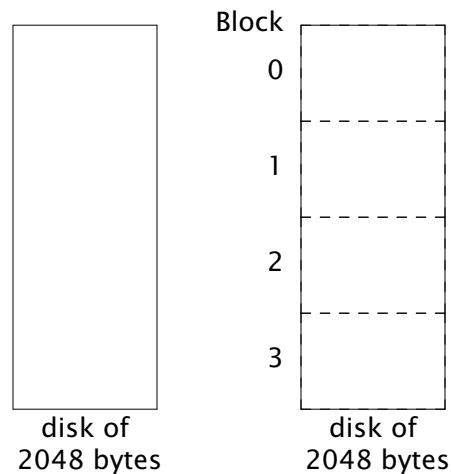

### Disk Contents

Mafs organizes and saves content on a disk as directories and files, just like any other filesystem.

The unit of storage is a logical block (not physical sector) of data. Disk space is split into blocks of 512 bytes. A directory entry uses 2 blocks (1KiB) and a data block could use upto 2048 blocks (1MiB).

A sample disk of 2048 bytes with 4 blocks.

A block is stored to the disk with a tag in the first byte and the Qid.path in the last 8 bytes. The different types of blocks on a disk are:

```
enum
{
    Tblank = 0,
    Tfree = 0,    /* free block */
    Tnone = 0,
    Tdata,        /* actual file contents */
    Tdentry,       /* directory entry, size = Dentrysize */
    /* Tdata & indirect blocks are last, to allow for greater depth */
    Tind0,         /* contains a list of Tdata block numbers for files
                  and Tdentry block numbers for directories.*/
    Tind1,         /* contains a list of Tind0 block numbers */
    Tind2,         /* contains a list of Tind1 block numbers */
    Tind3,         /* contains a list of Tind1 block numbers */
    Tind4,         /* contains a list of Tind1 block numbers */
    /* gap for more indirect block depth in future.
                  It can be put upto Tind7 without needing any code changes */
    Maxtind,       /* should be Tind0+Niblock */
    MAXTAG = Maxtind,

    Tmaxind = Maxtind - 1,
};
```

Every file or directory is represented on the disk by a directory entry (Dentry). A directory entry uses a unit sized block (tag = Tdentry) and is uniquely identifiable by a Qid.

A file's contents are stored in the directory entry itself if they are 320 bytes or lesser. A file stores its contents in blocks with a tag of Tdata if the file size is more than that. A directory holds the directory entries of its children in blocks each with a tag of Tdentry.

The blocks used by a file or directory entry are listed in their directory entry. As it is not possible to represent big files using the list of blocks available in the directory entry, the blocks are structured to use multiple levels of indirection as the file size increases.

A file's data blocks are identified by a tag of Tdata and that file's Qid.path. A directory's data blocks are identified by a tag of Tdentry and Qid.path of the child directory entry.

(Is this quirky? Should the child's directory entry have a tag with the parent's Qid.path?)

A block number of zero represents the end of the file's contents. If a file is truncated, the data and indirect blocks are given up and the dentry.dblocks[0] = 0.

Mafs does not store the last access time of a file or directory.

A directory entry is defined as:

```
enum {    Blocksize = 512ULL,      /* minimum data unit size */

    Metadataunits = 2,
    Metadatablocksize = Metadataunits*Blocksize, /* Keep the original and a copy together */

    Maxdatablockunits = 2048,
    Nindperblock = (Blocksize-3*sizeof(u64))/sizeof(u64), /* number of pointers per block */
    Nu64perblock = (Blocksize/sizeof(u64)),      /* number of u64's in a block */
    Dpathidx = (Blocksize/sizeof(u64) -1),      /* index of path in the last data block, last u64 */

    Namelen = 127,      /* maximum length of a file name, calculated manually */
    Ndblock = 32,      /* number of direct blocks in a Dentry */
    Niblock = 5,      /* maximum depth of indirect blocks, can increase it to 8 without issues */
};

struct Dentryhdr
{
    u8 tag;
    u8 verd;
    s16 uid;
    s16 gid;
    s16 muid;      /* 8 */
    u64 size;      /* 0 for directories. For files, size in bytes of the content - 16 */
    u64 pdblkn; /* block number of the parent directory entry. Will be 0 for root. - 24 */
    u64 pppath; /* parent path - 32 */
    u64 mtime; /* modified time in nano seconds from epoch - 40 */
    u64 qpath; /* unique identifier Qid.path 48 */
    u32 version; /* Qid.version 52 */
    u32 mode; /* same bits as defined in /sys/include/libc.h:/Dir.mode/ - 56 */
    u8 namelen; /* store name as a counted string 57 */
    s8 name[Namelen]; /* Namelen = 127 - 184 */
};

struct Datahdr
{
    u8 tag;
    u8 unused; /* for alignment and future use */
    u16 len;
    u64 dblkn; /* block number of the directory entry */
};

enum {
    /* size of identifiers used in a Tdata block */
    Ddataidssize = sizeof(Dentryhdr) - sizeof(u64 /* trailing path */),
    /* max possible size of data that can be stuffed into a Dentry */
    Ddatasize = Blocksize - Ddataidssize,
    Maxdatablocksize = Maxdatablockunits*Blocksize - Ddataidssize,
};
```

```
struct Dentry
{
    Dentryhdr;
    union
    {
        struct
        {
            u64 dblocks[Ndblock]; /* direct blocks. */
                                   /* List of Tdata block numbers for files and
                                   Tdentry block numbers for directories */
            u64 iblocks[Niblock]; /* indirect blocks */
        };
        Super;

        /* when size <= Dentrysize-184-sizeof(Tag), store the data here itself */
        s8 buf[Ddatasize];
    };
    u64 path; /* same as qid.path */
};
struct Indirect
{
    u8 tagi; /* the suffix i to avoid union complaining about ambiguous fields */
    u8 veri;
    u8 pad[6]; /* unused, to align to a multiple of 8 */
    u64 dblkno; /* block number of the directory entry */
    u64 bufa[Nindperblock];
    u64 path; /* same as qid.path */
};
struct Metadataunit
{
    union
    {
        Indirect;
        Dentry;
    };
};
struct Metadata
{
    union
    {
        Indirect i[2];
        Dentry d[2];
    };
};
struct Data /* used to unmarshall the disk contents */
{
    Datahdr;
    u8 buf[1]; /* upto Maxdatablocksize, followed by u64 path */
    /* u64 path; same as path at the end of the data content */
};
```

A directory entry once assigned is not given up until the parent directory is removed. It is zero'ed if the directory entry is removed. It is reused by the next directory entry created under that parent directory. This removes the need for garbage collection of

directory entries on removals and also avoids zero block numbers in the middle of a directory entry's list of blocks. A zero block number while traversing a directory entry's dblocks or iblocks represents the end of directory or file contents. When a directory is removed, the parent will have a directory entry with a tag of Tdentry and Qpnone and the rest of the contents set to zero.

A directory entry is stored in two blocks to have a copy on write. These entries are in consecutive blocks.

A directory's size is always zero.

iblocks[0] holds the block number of a Tind0 block. A Tind0 block contains a list of Tdata block numbers for files or a list of Tdentry block numbers for directories.

iblocks[1] has the block number of a Tind1 block. A Tind1 block contains a list of Tind0 block numbers.

Similarly, for other iblocks[n] entries, iblocks[n] has the block number of a Tind $n$  block. A Tind $n$  block contains a list of Tind( $n-1$ ) block numbers.

### Relative index

The zero'th relative index in a directory entry is the first data block. The next relative index is the second data block of the directory entry, and so on.

tests/6.reli shows how a relative index (reli) is translated into an actual disk block number.

To find the actual block number where the first block (zero'th as zero indexed) of a file is stored:

```
tests/6.reli 0 # command, below is the output of this command
reli 0
dblock[0]
```

To find the actual block number where the second block of a file is stored:

```
tests/6.reli 1
reli 1
dblock[1]
```

And so on, for the 32nd and 33rd blocks of a file:

```
tests/6.reli 31
reli 31
dblock[31]
```

```
tests/6.reli 32
reli 32
iblock[0] tagstartreli 32
Tind0 reli 0 is at [0] nperindunit 1
```

System Files	
Block	Description
0	magic dir entry and data
2	/adm/config dir entry
4	/adm/super dir entry
6	/adm/ dir entry
8	/adm/users/ dir entry
10	/adm/bkp/ dir entry
12	/adm/users/inuse dir entry
14	/adm/frees dir entry
16	/adm/ctl dir entry -- virtual file, empty contents
18	/adm/users/staging dir entry
20	/ direntry

The /adm/ctl file is used to halt or sync the file system. /adm/users is a r/w file that will reload users when written to it. The owner of the /adm/ctl file or any user belonging to the sys group can read the disk.

There is no /adm/magic directory entry as the block number of the magic block is zero and zero block in a directory entry signifies the end of the directory contents.

#### Backup blocks

A copy of Config, Super and Root blocks is maintained. This ensures a backup of config, Super and root blocks.

The backup block numbers on the disk are calculated during read based on the disk size.

Block	Description	Backup Block
2	/adm/config	last block number -2
4	/adm/super	last block number -4
20	/	last block number -6

Mafs needs at least  $N_{minblocks} = 28$  blocks (14 KiB).

kfs and cwfs use 8192 byte blocks. Hence, they store multiple directory entries (Dentry) per block. They use slot numbers to identify a particular directory entry in a block of directory entries. Mafs avoids that by using 512 byte blocks thus having only one directory entry per block. This avoids locking up other sibling directory entries on access.

#### Users

Users are defined in /adm/users/inuse file. Any changes to it are made through the /adm/users/staging file. All changes are written to the staging file and then inuse file is updated by writing the command users to the /adm/ctl file.

Either all changes to /adm/users/inuse are installed or nothing is installed from the /adm/users/staging file.

The format of /adm/users/inuse is described in users(6).

### **Buffer cache – Hash buckets with a circular linked list of lobuf's for collisions.**

An lobuf is used to represent a block in memory. An lobuf is unique to a block. All disk interaction, except for free block management, happens through an lobuf. We read a block from the disk into an lobuf. To update a block on the disk, we write to an lobuf, which, in-turn gets written to the disk.

An lobuf is protected by a read-write lock (RWlock). This ensures synchronization across multiple processes updating the same file.

getbuf(), putbuf(), putbufs() and putbuffree() are used to manage lobuf's. The contents of an lobuf is not touched unless it is locked by getbuf(). It is unlocked by putbuf(), putbufs() or putbuffree() calls. The lobuf.dirties Ref is decremented by the mafs writer's dowrite() without a lock(). This is to avoid deadlocks between putbuf() and the writer especially when the writer queue is full.

allocblock() allocates a free block into an lobuf. allocblocks() allocates a bunch of free blocks with their own lobuf's.

freeblock() erases the lobuf and returns the block to the free block management routines.

lobuf's are organized into a list of hash buckets to speed up access.

```
Hiob *hiob = nil;    /* array of nbuckets */
struct Hiob          /* Hash bucket */
{
    lobuf* link;      /* least recently used lobuf in the circular linked list */
    QLock;            /* controls access to this hash bucket */
    u64 n;             /* count of lobuf's in the circular list */
};
struct lobuf
{
    Ref;
    RWLock;           /* controls access to this lobuf */
    u64 blkno;         /* block number on the disk, primary key */
    u16 len;           /* number of Units */
    lobuf *fore;       /* for lru */
    lobuf *back;       /* for lru */
    union{
        u8 *xiobuf;   /* "real" buffer pointer */
        Data *io;
        Metadata *m;
    };
    Metadataunit *cur; /* this has the current Indirect or Dentry values */
    Metadataunit *new; /* use this unit for Indirect or Dentry changes */

    u8 *append;        /* appended data added not yet written to disk */
    u64 appendsize;
    u8 freshalloc;     /* uninitialized blocks on the disk */
    u64 atime;         /* to find old buffers to flush to the disk */
};
```

```
    u8 tag;  
};
```

The lobuf's are arranged into a list of hash buckets. Each bucket points a circular linked list of lobuf's to handle collisions. If all the lobuf's in the circular linked list are locked, new lobuf's are added to this linked list. This circular list is ordered on a least recently used basis. lobuf's once added to this list are not removed. When an lobuf is not in the list, the oldest unlocked lobuf is reused.

Hiob hiob[nbuckets] is a valid representation of the list of hash buckets. The block number is hashed to arrive at the relevant hash bucket index.

hiob[hash(block number)].link = Address of lobuf0, where lobuf0 is the least recently used lobuf.

The size of the buffer cache is: number of hash buckets \* collisions per hash bucket \* block size. The approximate size of the buffer cache = Nbuckets \* Ncollisions \* Raw-blocksize = 256 \* 10 \* 512 bytes = 1.28GiB. The -h parameter can be used to change the number of hash buckets.

If you have RAM to spare, increase Nbuckets instead of Ncollisions as the hash index lookup is faster than searching through a linked list.

lobuf.Ref is used to avoid locking up the hash bucket when a process is waiting for a lock on an lobuf in that hash bucket.

lobuf.Ref ensures that an lobuf is not stolen before another process can get to wlock()'ing it after letting go of the lock on the hash bucket. We cannot hold the lock on the hash bucket until we wlock() the iobuf as that blocks other processes from using the hash bucket. This could also result in a deadlock. For example, the directory entry is block 18, which hashes to a hash index of 7. A writer() locked the directory entry iobuf and wants to add a data block 84 to the directory entry. Block 84 hashes to the same hash index of 7. Another process wanting to access the directory entry is waiting for a lock on that io buffer. While doing so, it has locked the hash bucket. Now, this has caused a deadlock between both these processes. The first process cannot proceed until it can lock the hash bucket holding block 84 and is still holding the lock on the directory entry in block 18. The second process cannot lock block 18 and is holding the lock on the hash bucket.

for locking a buffer:

```
    qlock(hash bucket); incref(buffer); qunlock(hash bucket);  
    wlock(buffer); decref(buffer);
```

for stealing an unused buffer:

```
qlock(hash bucket);
find a buffer with ref == 0 and wlock()'able.
qunlock(hash bucket);
```

```
for unlocking a buffer:
    wunlock(buffer);
```

## Free blocks

Free blocks are managed using Extents. The list of free blocks is stored to the disk when shutting down. If this state is not written, then the file system needs to be checked and the list of free blocks should be updated.

When shutting down, the Extents are written to free blocks. This information can be accessed from /adm/frees. Also, fsok in the super block is set to 1. Mafs does not start until fsok is 1. When fsok = 0, run the sanity check that the unused blocks and the free blocks in /adm/frees match up. disk/reconcile identifies any missing blocks or blocks that are marked as both used and free.

This process of fixing issues and setting fsok to 1 is manual. There is no automatic file system checker as in other file systems. This document aims to empower you with the knowledge to fix your file system issues instead of entrusting your precious data to an arbitrary decision maker such as the file system checker.

A tag of Tfree and Qpnone represent a free block. If a directory entry is removed, the parent will have a zero'ed out child directory entry (Qid.path = 0) and a tag of Tdentry and Qpnone.

## Extents

Free blocks and memory are managed using Extents, an abstraction used to manage a continuous list of items.

An Extent represents a continuous list of items. An Extents is a list of such Extent's.

```
struct Extent {
    struct Extent *low, *high; /* sorted by start */
    u64 start;                 /* where this extent starts from */
    u64 len;                   /* how many units in this extent */

    /* circular least recently used linked list limited to Nlru items */
    struct Extent *prev, *next;
};

struct Extents {
    Extent *head; /* find the first block in a jiffy */
    QLock lck;
    u32 n;         /* number of extents */
    Rendez isempty; /* fully used, nothing available */

    u8 nlru; /* number of items in the lru linked list */
    Extent *lru; /* least recently used extent in the circular lru linked list */
    char name[32];
};
```

```
void (*flush)(void);
};
```

To allocate n items from Extents, we find the lowest (by block number or memory address) extent that can satisfy our request. If a bigger Extent is available, slice it and take the portion we need.

If there is no available Extent to satisfy our request, panic().

allocblock() and freeblock() use balloc() and bfree() respectively. balloc() assigns blocks from an extent and bfree() adds them to an extent for next allocation.

Kfs stores the list of free blocks in a Tfreels block and the Superblock. Instead we use block management routines, similar to pool.h, to allocate and monitor free blocks. On shutdown(), the block management routines (extents.[ch]) store state into the free blocks. This can be read from /adm/frees. On startup, this is read back by the block management routines. On a crash, the fsck can walk the directory structure to identify the free blocks and recreate /adm/frees.

## Code details

Program	Description
disk/mafs	Start mafs on a disk.
disk/free	List the free blocks. It reads the contents of /adm/frees.
disk/used	List the used blocks by traversing all directory entries.
disk/block	Show the contents of a block.
disk/unused	Lists the unused blocks when given extents of used blocks.
disk/updatefrees	Update the contents of /adm/frees.

File	Description	chatty9p
9p.c	9p transactions	2
blk.c	routines to show blocks.	
console.c	obsolete. /adm/ctl is the console.	
ctl.c	/adm/ctl operations.	
dentry.c	encode/decode the file system abstraction into block operations.	3
extents.[ch]	routines to manage the free blocks.	6
iobuf.c	routines on lobuf's. The bkp() routines operate on lobuf's.	5
sub.c	initialization and super block related routines.	2
tag.c	routines to manage a relative index (reli) in a directory entry.	
user.c	user management routines.	

A Chan's state could get out of sync with the contents if another process changes the on-disk state. Ephase error occurs when that happens.

For throughput, multiple processes are used to service 9p i/o requests when the -s flag is not used.

### Useful commands:

Ream and start single process Mafs on a disk and also mount it for use.

```
mount -c <{disk/mafs -s -r mafs_myservice mydisk <[0=1]} /n/mafs_myservice
-s: use stdin and stdout for communication
-r mafs_myservice: ream the disk using mafs_myservice as the service name
mydisk: running mafs on the disk, mydisk
```

Ream and start multiple-process mafs on a disk.

```
disk/mafs -r mafs_myservice mydisk
mount -c /srv/mafs_myservice /n/mafs_myservice
```

Ream and start mafs on a file. Also, mount the filesystem at /n/mafs\_myservice.

```
dd -if /dev/zero -of myfile -bs 512 -count 128 # 64KB file
mount -c <{disk/mafs -s -r mafs_service myfile <[0=1]} /n/mafs_myservice
```

```
# to reuse the contents of myfile later, remove -r (ream) from the above command.
mount -c <{disk/mafs -s myfile <[0=1]} /n/mafs_myservice
```

Prepare and use a disk (/dev/sdF1) for mafs.

```
disk/fdisk -bawp /dev/sdF1/data # partition the disk
echo '
a fs 9 $-7
w
p
q' | disk/prep -b /dev/sdF1/plan9 # add an fs plan 9 partition to the disk
disk/mafs -r mafs_sdF1 /dev/sdF1/fs # -r to ream the disk
mount -c /srv/mafs_sdF1 /n/mafs_sdF1

# for using the mafs file system on the disk later on
disk/mafs /dev/sdF1/fs # no -r
mount -c /srv/mafs_sdF1 /n/mafs_sdF1
```

Starting mafs on a 100 MiB file. The below commands create a disk.file to use as a disk. Mount /n/mafs\_disk.file for the file system.

```
dd -if /dev/zero -of disk.file -bs 1m -count 100;
mount -c <{disk/mafs -s -r mafs_disk.file disk.file <[0=1]} /n/mafs_disk.file
```

Starting mafs on a RAM file. The below commands create a ramfs filesystem to use as a disk.

```
ramfs -m /n/mafs_ramfs
touch /n/mafs_ramfs/file
dd -if /dev/zero -of /n/mafs_ramfs/file -count 100 -bs 1m
disk/mafs -r mafs_ramfs_file /n/mafs_ramfs/file
mount -c /srv/mafs_ramfs_file /n/mafs_ramfs_file
```

Sync Mafs. This command does not return until all the writes are written to the disk. So, could take a long time if you have a long writer queue.

```
echo sync >> /n/mafs_myservice/adm/ctl
```

Stop Mafs: There are 2 ways to shutdown:

1. Unmount and remove the /srv/mfs\_service file (can be rm and unmount too).
2. Write halt into the /adm/ctl file. Unmount() the mafs file system to keep it clean.

In the first instance, the srv() process is driving the shutdown. It calls fsend(). rm /srv/mfs\_service file does not wait for fsend() to finish. Hence, there is no way to ensure that memory contents have been flushed to the disk. If the system is shutdown or restarted immediately, there is a very high possibility that the filesystem will be in an inconsistent state.

In the second instance, `fsend()` is called by the worker process. It does not return until all the pending writes have been flushed to the disk. It also removes the `/srv/mafs_service` file and also stops the `srv()` process. Hence, this is the preferred approach to shutting down the file system.

There is no way to `unmount()` automatically on shutdown. The `mount()` and `unmount()` calls are client driven and it is not the responsibility of the server to find all the clients that mounted it. Just shutdown and let the respective clients deal with their mess.

The below command does not return until all the writes are written to the disk. So, could take a long time if you have a long writer queue. This is the proper way to shutdown the `mafs` file system.

```
echo halt >> /n/mafs_myservice/adm/ctl
```

Interpret the contents of a block based on the tag and write out a single formatted block based on the tag

```
disk/block tests/test.0/disk 22
```

Traverse the directory heirarchy and write out all the used block numbers. `disk/reconcile` uses the output of this to reconcile the list of used blocks with the list of free blocks. Also, writes the invalid blocks to `stderr`. Starting from root, walk down each directory entry printing out the linked blocks with invalid tags. (Why not just write out the list of dirty blocks too? instead of using a different command for it?)

```
disk/used tests/test.0/disk
```

From the contents of `/adm/frees` show the list of free blocks. `disk/reconcile` uses the output of this to reconcile the list of used blocks with the list of free blocks.

```
disk/free tests/test.0/disk
```

Read two lists of block numbers and flag the common and missing blocks.

```
disk/reconcile -u <{disk/used tests/test.0/disk} \  
-F <{disk/free tests/test.0/disk} 32
```

Find traverses the directory heirarchy and identifies the file that a block number belongs to.

```
disk/find tests/test.0/disk 17
```

Find the total number of blocks on a disk.

```
dd -if /dev/sdF1/fs -bs 512 -iseek 2 -count 1 -quiet 1 | awk '$1 == "nblocks" { print $2 }'  
disk/block /dev/sdF1/fs 2 | awk '$1 == "nblocks" { print $2 }'
```

Build the list of free blocks. This should match the contents of `/adm/frees`.

```
disk/unused 11721040049 <{disk/used /dev/sdF1/fs} # 11721040049 = total number of disk blocks  
disk/unused 32 <{disk/used test.0/disk} # 32 = total number of disk blocks
```

Change the contents of /adm/frees.

```
disk/updatefrees tests/test.0/disk <{disk/unused 32 <{disk/used tests/test.0/disk}}
disk/updatefrees /dev/sdF1/fs <{disk/unused 11721040049 <{disk/used /dev/sdF1/fs}}
```

A sanity check that the file system is not corrupt by comparing that the unused blocks and free blocks match up. \$nblocks is the total number of disk blocks. \$disk is the disk.

```
diff <{disk/unused -l 32 <{disk/used tests/test.0/disk}} <{disk/free tests/test.0/disk}
```

Check and correct a crashed filesystem.

```
disk=/dev/sdF1/fs
nblocks='{disk/block /dev/sdF1/fs 2 | awk '$1 == "nblocks"{ print $2 }'}
```

```
disk/updatefrees /dev/sdF1/fs <{disk/unused $nblocks <{disk/used /dev/sdF1/fs}
disk/fsok /dev/sdF1/fs
```

```
disk=/dev/sdF1/fs
nblocks='{disk/block $disk 2 | awk '$1 == "nblocks"{ print $2 }'}
```

```
disk/updatefrees $disk <{disk/unused $nblocks <{disk/used $disk}
disk/fsok $disk
```

## Tests

Program	Description
tests/regress.rc	All regression tests
tests/chkextents.rc	Unit tests on extents
tests/chkreli.rc	Unit tests on relative index lookups
tests/chknlastdatablocks.rc	Unit tests on the number of blocks in the last Tdata block
tests/6.offsets	Write file using different offsets to test mafswrite()
tests/6.sizes	Show the effects of the different parameters
tests/6.testextents	Test extents.[ch] state changes
tests/6.reli	Translate relative index to block number on a disk

The below disk state tests:

1. Initialize a disk for mafs.
2. Run mafs on that disk.
3. Stop mafs.
4. Compare the contents with the expected contents (tests/test.0/blocks/\*).

Disk State	
Test	Description
tests/test.0	empty disk
tests/test.1	create a file /dir1/file1 and echo test into it
tests/test.2	writes at different offsets to a file and then removes the file
tests/test.3	write, read and delete files with sizes upto 16384 blocks
tests/test.4	directory copy
tests/test.5	fcg gzipped files
tests/test.6	df
tests/test.7	multiple processes working on the filesystem simultaneously
tests/test.8	check backup blocks locations
tests/test.9	examples used by this document
tests/test.a	write, read and delete a 100MB file
tests/test.b	duplicate of test.2 but seeded with random data
tests/test.d	seed with random data and do mkdir -p a/b/c/d/e/f/g/h
tests/test.e	seed with random data and test directory and file deletions
tests/test.f	test restart

Extents behaviour	
Test	Description
tests/extents/addabove	Figure 1 of the Extents section
tests/extents/addabove1	Figure 2 of the Extents section
tests/extents/addbelow	Figure 3 of the Extents section
tests/extents/mergeabove	Figure 4 of the Extents section
tests/extents/mergenext	Figure 5 of the Extents section
tests/extents/mergeprevious	Figure 6 of the Extents section

To run all the regression tests:

```
cd tests; ./regress.rc
```

To loop through all the blocks of a test:

```
for(t in tests/test.2/blocks/^{seq 0 39}*){ echo $t; echo '-----'; cat $t; echo }
```

### Performance metrics

```
ramfs -m /n/ramfs

```

Profiling instructions:

```
Set LDFLAGS=-p in the mkfile and install the executables.
profilesize=2000000
ramfs -m /n/ramfs
touch /n/ramfs/file
dd -if /dev/zero -of /n/ramfs/file -count 700 -bs 1m
mount -c <{disk/mafs -s -r mafs_disk.file /n/ramfs/file <[0=1]} /n/mafs_ramfs_file
cat /dev/zero | tput -p > /n/mafs_ramfs_file/zeros.file
    57.94 MB/s
    55.27 MB/s
    46.67 MB/s
echo halt >> /n/mafs_ramfs_file/adm/ctl; lc /srv
```

## Limitations

As we use packed structs to store data to the disk, a disk with mafs is not portable to a machine using a different endian system.

## Design considerations

For exclusive use (mode has DMEXCL bit set) files, there is no timeout.

Use an fs(3) device for RAID or other configuration involving multiple disks.

Why are you not using a checksum to verify the contents?

Checksums are probabilistic and can be implemented as a bespoke application instead of complicating the file system implementation.
